INTRODUCTION

For structures exposed to damaging environments the structural performance must be considered as time-dependent, mainly because of the progressive deterioration of the mechanical properties of materials which makes the structural system less able to withstand the applied actions. Therefore, a consistent approach to optimum design of durable structures should lead to find design solutions able to comply with the desired performance not only at the initial time of construction, but also during the whole expected service lifetime by taking into account the effects induced by unavoidable sources of mechanical damage and by eventual maintenance interventions.

This paper presents a new conceptual approach to the lifetime optimization of deteriorating structures under multiple loading conditions (Azzarello et al. 2006, Biondini and Marchiondelli 2006a).

The structural damage is modeled by introducing a proper material degradation law and the structural analysis is carried out at different time instants in order to assess the time evolution of the system performance. The design constraints are related to both the time-variant stress and displacement state, as well as to the amount of structural damage. The objective function is formulated by accounting for both the initial cost of the structure and the costs of possible maintenance interventions, that are properly discounted over time and assumed to be proportional to the actual level of structural damage. The proposed procedure is initially presented for truss and framed structures made by homogeneous members. Finally, it is extended to the case of reinforced concrete structures by adopting different damage rates and material costs for both concrete and steel.

The lifetime structural optimization of a steel truss and of a reinforced concrete frame under different damage and maintenance scenarios proves the effectiveness of the proposed formulation. In particular, the obtained results highlight the fundamental role played by both the time-variant performance and the maintenance planning in the selection of the optimum structural design.

MODELING OF STRUCTURAL DAMAGE

With reference to truss and framed structures, damage is considered to affect the cross-sectional area $A=A(t)$, the elastic modulus $E=E(t)$, and the material strength $\sigma = \sigma(t)$ of each member:

$$A(t) = [1 - \delta_A(t)]A_0, \quad E(t) = [1 - \delta_E(t)]E_0, \quad \sigma(t) = [1 - \delta_\sigma(t)]\sigma_0$$

(1)
$\delta(t) = \delta(t)$

Figure 1. Modeling of structural damage. (a) Time evolution of the damage index $\delta = \delta(t)$. (b) Linear relationship between the rate of damage and the stress level $\sigma = \sigma(t)$. (c) Meaning of the damage parameter $T_\delta$.

where $\delta, \delta_c, \delta_m, \sigma$ are dimensionless damage indices which provide a direct measure of the damage level within the range $[0; 1]$. Proper correlation laws may be introduced to define the corresponding variation of other geometrical properties of the cross-section, like the inertia moment, etc.

The time evolution of the damage indices $\delta, \delta_c, \delta_m$ clearly depends on the physics of the deterioration process, usually related also to the stress state $\sigma = \sigma(t)$ (Figure 1.a). Therefore, a reliable assessment of the decreasing structural performance during time requires the formulation of deterioration models suitable to describe the actual damage evolution and its interaction with the structural behavior (Biondini et al. 2004). However, despite the inherent complexity of damage laws, very simple degradation models could be successfully adopted in order to define an effective hierarchical classification of the design alternatives (Biondini and Marchiondelli 2006b).

Without any loss of generality, in this study it is assumed that all material properties undergo the same damage process, or $\delta = \delta_c = \delta_m = \delta$. In addition, the damage index $\delta = \delta(t)$ is correlated to the time-variant structural behavior by assuming the following relationship between the rate of damage and the acting stress $\sigma = \sigma(t)$ (Figure 1.b):

$$\frac{d\delta(t)}{dt} = \frac{1}{T_\delta} \left[ \frac{\sigma(t)}{\sigma_0} \right]^\alpha \begin{cases} \sigma_0^- & \text{if } \sigma \geq 0 \\ \frac{\sigma_0^-}{\sigma_0} & \text{if } \sigma < 0 \end{cases}$$

(2)

where $\alpha \geq 0$ is a suitable constant, $\sigma_0^+$ and $\sigma_0^-$ are the minimum and maximum allowable stress at the initial time $t = t_0$, respectively, and $T_\delta$ represents the time period required for a complete damage under a constant stress level $\sigma(t) = \sigma_0$ (Figure 1.c). In addition, the initial condition $\delta(t_0) = 0$ with $t_0 = \max \{t \mid \sigma(t) \leq \sigma_c \}$ is assumed, where $\sigma_c = \sigma_0$ is a critical stress threshold.

The index $\delta = \delta(t)$ fully describes the damage evolution in each point of the structure. However, due to its local nature, it does not seem handy for design purposes. A more synthetic global measure of damage $\tilde{\delta} = \tilde{\delta}(t)$ may be easily computed as the average of $\delta$ over the volume of the whole structural system (Biondini 2004, Azzarello et al. 2006).

3 LIFETIME OPTIMALITY CRITERIA

3.1 Structural Cost

Several quantities able to represent the structural performance may be chosen as targets for the optimal design. In the following, the adopted design target is the total cost $C$ of the structure over its service lifetime, given by the sum of the initial cost $C_0$ and maintenance cost $C_m$:

$$C = C_0 + C_m$$

(3)

The initial cost $C_0$ is computed as follows:

$$C_0 = cV_0$$

(4)

where $V_0$ is the total volume of material and $c$ is the corresponding unit cost. The maintenance cost $C_m$ can be evaluated by summing the costs of the individual interventions:

$$C_m = \sum_{k=1}^{r} \frac{C_m^k}{(1 + v)^{(t_0 - t_0)}}$$

(5)

where the cost $C_m^k$ of each intervention $k = 1, \ldots, r$ has been referred to the initial time $t_0$ by taking a proper discount rate $v$ into account (Kong and Frangopol 2003).
3.2 Maintenance Scenario

The previous general formulation is now specialized to a prescribed maintenance scenario. In this scenario an essential maintenance aimed to totally restore the initial structural performance is performed after each design period $T_D$, or at each time instant $t_k = (t_0 + kT_D)$. In this way, all the interventions have the same cost $C_m = C_m^0$, and the total number of interventions applied during a prescribed service lifetime $T_S$ is $r = \lceil \text{int}(T_S/T_D) \rceil - 1$. Therefore, the cost of maintenance is:

$$C_m = C_m^0 \sum_{k=1}^{r} \frac{1}{(1 + v)^{kT_D}} = C_m^0 q$$

(6)

where the factor $q=q(T_S,T_D,v) \leq r$ depends on the prescribed parameters $T_S$, $T_D$, and $v$ only.

The cost $C_m^i$ of the single intervention is related to the level of structural damage developed during each design period $T_D$. Since damage is not recovered during time, a measure of this damage is given by the global damage index $\delta = \delta(t)$ evaluated at the end of each design period $T_D$, or:

$$\tilde{\delta} = \hat{\delta}(t_k) = \hat{\delta}(t_{k-1} + T_D), \quad k=1,\ldots,r$$

(7)

Based on the lifetime global damage index $\tilde{\delta}$, the following linear relationship is assumed:

$$C_m^i = C_0 \hat{\delta}$$

(8)

and the total lifetime structural cost $C$ is finally formulated as follows:

$$C = C_0 (1 + \tilde{\delta} q)$$

(9)

3.3 Role of Maintenance Cost

To highlight the actual role played by a prescribed maintenance program, the design of the tensioned bar shown at the top of Figure 2 is investigated. By denoting with $d_0$ the diameter of the undamaged cross-section, the total cost of the bar over the prescribed service lifetime $T_S$ is:

$$C = C_0 (1 + \tilde{\delta} q) = cA_oL(1 + \tilde{\delta} q) = c \frac{\pi d_0^2 L}{4} (1 + \tilde{\delta} q)$$

(10)

with $\tilde{\delta} = \tilde{\delta}(d_0)$. The diameter $d_0$ must be chosen in such a way that the acting stress $\sigma = \sigma(t)$ is no larger than the admissible stress $\bar{\sigma} = \bar{\sigma}(t)$ over the prescribed design period $T_D$:

$$\sigma(t) = \frac{F}{A(t)} = \frac{F}{A_o[1 - \delta(t)]] = \frac{4F}{\pi d_0^2 [1 - \bar{\delta}(t)]} \leq \bar{\sigma}(t) = \bar{\sigma}_o[1 - \delta(t)]$$

(11)

with $\delta(t) = \delta(d_0,t)$. In case damage is not considered ($\delta = \tilde{\delta} = 0$), the minimum cost solution $d_0^*$ is simply given by the minimum diameter $d_0$ which satisfies the stress constraint:

$$d_0^* = d_{0,\text{min}} = \sqrt{\frac{4F}{\pi \bar{\sigma}_o}}$$

and

$$C^* = C(d_0^*) = C_0(d_0^*) = c \frac{F L}{\bar{\sigma}_o}$$

(12)

On the contrary, when damage is properly included in the design problem, the minimum cost solution $d_0^*$ is, in general, no longer associated with the diameter $d_{0,\text{min}}$. In fact, higher $d_0^*$-values may be required to achieve a balance between the maintenance cost and the amount of damage.

These aspects are highlighted in Figure 2, where both the cost and structural efficiency of the bar versus its diameter $d_0$ are shown for different values of the damage rate $\theta = T_S/T_o$, with $\sigma_o=0$, $\alpha=1$, and with reference to the following case study: $F=70$ kN, $\bar{\sigma}_o=100$ MPa, $T_S=100$ years, $T_D=10$ years, and $v=0$ ($q=r$). In particular, the diagrams shown in Figure 2 refer to the following quantities:

$$\chi_0^* = C_0/C^*, \quad \chi_m^* = C_m/C^*, \quad \chi^* = \chi_0^* + \chi_m^* \quad \rho = \sigma(T_D)/\bar{\sigma}(T_D)$$

(13)

where $C^*$ denotes the optimal cost without damage ($\theta=0$). The following remarks can be made:

- The minimum feasible diameter without damage is $d_{0,\text{min}}=29.9$ mm. Its value increases with $\theta$.
- The initial cost $\chi_0^*$ increases and the maintenance cost $\chi_m^*$ decreases when $d_0$ increases. For a given value of $d_0$, the maintenance cost $\chi_m^*$ increases with $\theta$.
- The total cost $\chi^*$ has a minimum for $d_0^* \geq d_{0,\text{min}}$, and the optimal diameter $d_0^*$ increases with $\theta$.
- The stress ratio $\rho$ decreases with $d_0$ and increases with $\theta$. The optimal solution $d_0^*$ at the end of the design period $T_D$ may be not fully stressed ($\rho \leq 1$).

Similar results are obtained by varying the parameter $T_D$ (Azzarello 2005).
4 LIFETIME STRUCTURAL OPTIMIZATION

4.1 Formulation of the Optimization Problem

The purpose of a one-target lifetime design process is to find a vector of design variables \( \mathbf{x} \in \mathbb{R}^n \) which optimizes the value of an objective function \( f(\mathbf{x}) \), according to both side constraints with bounds \( \mathbf{x}^{-} \) and \( \mathbf{x}^{+} \), and inequality time-variant behavioral constraints \( g(\mathbf{x}, t) \leq 0 \):

\[
\min_{\mathbf{x} \in D} f(\mathbf{x}) \quad \text{subject to} \quad \mathbf{x}^{-} \leq \mathbf{x} \leq \mathbf{x}^{+}, \quad g(\mathbf{x}, t) \leq 0
\]

Based on the previously introduced cost concepts, the objective function \( f(\mathbf{x}) \) to be minimized is related to the total lifetime cost \( C \) of the structure as follows:

\[
f(\mathbf{x}) \equiv C(\mathbf{x})/c = V_0(\mathbf{x})[1 + \delta(\mathbf{x})q]
\]

The time-variant behavioral constraints are related to the corresponding structural response by means of the stress \( \sigma_{i,j}(t) \) and displacement \( u_{i,j}(t) \) associated with each element \( i \), nodal point \( j \), and loading condition \( \ell \), as follows:

\[
\begin{cases}
\overline{\sigma}_{i,j}(\mathbf{x}, t) \leq \sigma_{i,j}(\mathbf{x}, t) \leq \overline{\sigma}_{i,j}(\mathbf{x}, t) \\
\overline{u}_{i,j}^{-} \leq u_{i,j}(\mathbf{x}, t) \leq \overline{u}_{i,j}^{+}
\end{cases}
\]

where \( \overline{\sigma}_{i,j}(t) \) and \( \overline{\sigma}_{i,j}^{-}(t) \) are the minimum and maximum allowable stress, respectively, \( \overline{u}_{i,j}^{-} \) and \( \overline{u}_{i,j}^{+} \) are prescribed displacement bounds, and \( \overline{\sigma}_{i,j}^{-} = \overline{\sigma}_{i,j}^{-}(t) \) is the critical stability threshold. Constraints on both local and global damage may be also introduced (Azzarello et al. 2006). This optimization problem is solved by using a gradient-based method (Vanderplaats, 2001).

4.2 The Case of Reinforced Concrete Structures

The general approach previously presented can be easily extended to the special case of reinforced concrete structures. First, the damage evolution in concrete and steel is described by means of two damage indices \( \delta = \delta(t) \) and \( \delta = \delta(t) \), respectively. Second, the initial cost \( C_0 \) is computed as follows:

\[
C_0 = c_0 V_{c,0} + c_s V_{s,0} = c_0 (V_{c,0} + \kappa V_{s,0}) = c_0 V_{c,0}
\]

where \( V_{c,0}, V_{s,0} \) are the total volumes of concrete and steel, respectively, \( c_0, c_s \) are the corresponding unit costs, \( \kappa = c_s/c_c \) is the unit cost ratio, and \( V_{c,0} \) is the equivalent volume of concrete. Finally, focusing the attention on the Serviceability Limit State (SLS), the time-variant behavioral constraints on the stress state associated with each loading condition \( \ell \) are related to the stress in both concrete fibers \( \sigma_{c,i,j}(t) = \sigma_{c,i,j}(t) \) and steel bars \( \sigma_{s,i,j}(t) = \sigma_{s,i,j}(t) \) of each element \( i \):

\[
\begin{cases}
\overline{\sigma}_{c,i,j}(\mathbf{x}, t) \leq \sigma_{c,i,j}(\mathbf{x}, t) \leq \overline{\sigma}_{c,i,j}(\mathbf{x}, t) \\
\overline{\sigma}_{s,i,j}(\mathbf{x}, t) \leq \sigma_{s,i,j}(\mathbf{x}, t) \leq \overline{\sigma}_{s,i,j}(\mathbf{x}, t)
\end{cases}
\]

Clearly, additional constraints related to the Ultimate Limit States (ULS) may be also introduced, even though they are not considered here.
5 APPLICATIONS

5.1 Steel Truss

The proposed formulation is applied to the lifetime optimization of the truss structure shown in Figure 3.a. Three alternative loading conditions are considered: (a) \( F_x=F_y=1 \text{ MN} \) and \( F_z=0 \); (b) \( F_x=0 \) and \( F_y=F_z \); (c) \( F_x=F_y=F_z \). It is worth noting that, in general, the response to the loading condition (c) is not given by the superposition of (a) and (b), since the system properties vary during time.

A circular cross-section with diameter \( d_i \) is assumed for each member \( i=1,\ldots,10 \). The structural shape is defined by the coordinates \((z_j,y_j)\) of each node \( j=1,\ldots,7 \). The design model is based on the following geometrical constraints: \( d_1=d_4, \ d_2=d_5, \ d_3=d_6, \ d_7=d_{10}, \ z_1=z_4=0; \ y_1=y_4, \ (z_2,y_2)=(z_5,y_5), \ (z_3,y_3)=(z_6,y_6), \ y_7=0, \ z_7=L=3 \text{ m} \). Therefore, the optimization problem is defined by \( n=10 \) design variables \( x=[d_1 \ d_2 \ d_3 \ d_8 \ d_9 \ y_1 \ z_2 \ y_2 \ z_3 \ y_3]^T \), for which the following side constraints are assumed: 0.05 m \( \leq d_i \leq 0.50 \text{ m} \); 0.10 m \( \leq y_j \leq 1.00 \text{ m} \); 0.10 m \( \leq z_2 \leq 2.80 \text{ m} \); 0.20 m \( \leq z_3 \leq 2.90 \text{ m} \).

For the behavioral constraints the initial allowable stress \( \sigma_{\text{uo},i} = -\sigma_{\text{uo},i} = \sigma_u = 160 \text{ MPa} \) is considered for each member \( i \) and loading condition \( \ell \).

In case damage is not considered, the optimal solution described in Figure 3.b and Table 1 is achieved. This solution is compared with the structures shown in Figure 4, obtained by solving the lifetime optimization problem with reference to a service lifetime \( T_S=100 \text{ years} \) and a damage rate \( \theta=T_d/T_S=10 \), with \( \sigma_u=0 \) and \( \sigma=1 \), for different design monitoring periods \( T_D=\{1, 50 \text{ years} \} \) and discount rates \( \nu=\{0, 3\% \} \). This comparison, together with the results obtained for other values of the parameters \( \nu \) and \( T_D \) (Azzarello, 2005), leads to the following general conclusions:

- The optimal design solution \( x^* \) strongly depends on both the parameters \( T_D \) and \( \nu \). In particular, both such parameters influence the optimal dimension of the cross-sections, while the \( \nu \)-values tend to significantly affect the optimal location of the nodal points only.
- The initial cost \( C_0^* \) strongly increases with \( T_D \), and does not significantly depend on \( \nu \).
- The maintenance cost \( C_{\text{m}}^* \) decreases with both \( T_D \) and \( \nu \).
- The total cost \( C^* \) increases with \( T_D \), and decreases with \( \nu \). This tendency highlights the expected higher cost-effectiveness of a maintenance planning with frequent interventions over more conventional maintenance-free design strategies.
- The lifetime damage index \( \delta^* \) increases with \( T_D \), and does not significantly depend on \( \nu \).
- Despite no constraints are imposed on the nodal displacements, the maximum deflection does not significantly depend on \( T_D \) and \( \nu \). In particular, the maximum vertical displacement of node 7 approximately equals the optimal value associated with the undamaged scenario \( (u_v=5.1 \text{ mm}) \).

Similar results are obtained by varying the parameter \( \theta \) in the range 0.50-20 (Azzarello, 2005). Clearly, higher \( \theta \)-values lead to more ponderous optimal structures and, consequently, to higher values of the optimal cost components.
5.2 Reinforced Concrete Frame

The previous formulation is applied to the lifetime optimization of the reinforced concrete frame shown in Figure 5.a. A rectangular cross-section is assumed for both beam and columns. With reference to Figures 5.a and 5.b, the optimization problem is defined by $n=9$ design variables $\mathbf{x} = [b, h_1, h_2, A_1, A_2, A_3, A_3', A_4', d]^T$, for which the following side constraints are assumed: $b \geq 300$ mm; $1 \leq h_i/b \leq 2$, $i=1,2; A_i \geq 2\varnothing 12$ and $A_i' \geq 2\varnothing 12$, $i=1,2,3; 0.10 \leq d/L \leq 0.50$.

Figure 6. Reinforced concrete frame. Loading conditions.

Figure 7. Reinforced concrete frame. Optimal design solutions associated with the damage scenarios described in Table 2 ($\theta = T_\delta / T_\delta = 10$, $T_\delta = 100$ years, $T_D = 10$ years, $\kappa = 20$, $v = 3\%$).
The three alternative loading conditions shown in Figure 6 are considered. Since the SLS is investigated, the time-variant structural response in terms of nodal displacements and internal stress resultants are evaluated by assuming a linear elastic behavior. Based on the general criteria for concrete design, the corresponding stress in the materials are computed at the cross-sectional level by assuming for concrete a linear elastic behavior in compression with \( E_c = 30 \) GPa and no strength in tension (\( \sigma_c = 0 \)), and for steel a linear elastic behavior in both tension and compression with \( E_s = 15E_c \).

The same behavioral constraints are considered for each loading condition. The stress in the materials is verified in each member by assuming the initial allowable stress \( \sigma_{c,i} = 150 \) MPa for concrete, and \( \sigma_{s,i} = 1800 \) MPa for steel. The displacement constraints \( u_x \leq 20 \) mm and \( u_y \leq 10 \) mm over the whole service lifetime are also considered (Figure 5.a).

The lifetime performances are defined by the following parameters: service lifetime \( T_S = 100 \) years, design period \( T_D = 10 \) years, unit cost ratio \( \kappa = 20 \), discount rate \( \nu = 3\% \), and damage rate \( \theta = T_S / T_D = 10 \), with \( \sigma_{c,i} = 0 \) and \( \sigma_{s,i} = 1 \) for both concrete and steel. Moreover, to investigate the role of the spatial distribution of deterioration, the damage scenarios described in Table 2 are considered.

The direct comparison of the optimal solutions shown in Figure 7 shows that the optimal dimensions of the cross-sections, as well as the optimal amount and distribution of reinforcement, strongly depend on the prescribed damage scenario. In particular, it is worth noting that damage leads to a more ponderous design not only for members affected by deterioration. In fact, due to redundancy, damage induces a time-variant redistribution process in which the internal stress resultants tend to progressively move towards the undamaged members.

6 CONCLUSIONS

A new conceptual approach to the minimum lifetime cost of deteriorating structures under multiple loading conditions has been presented. This approach allowed to overcome the inconsistencies involved in the classical formulation of the optimum design problem, where the time evolution of the structural performance induced by the progressive deterioration of the system properties is not adequately considered. In fact, in the proposed formulation, the structural damage is accounted for by means of a proper material degradation law of the mechanical properties, and the design constraints of the optimization problem are related to the corresponding time-variant structural performance over the whole expected service lifetime of the construction. In addition, the objective function is formulated by accounting for both the initial cost of the structure and the costs of possible maintenance interventions, that are properly discounted over time and assumed to be proportional to the actual level of structural damage.

The lifetime optimization of a steel truss and of a reinforced concrete frame proved the effectiveness of the proposed approach by highlighting that the optimal solution strongly depends on both the time-variant structural performance and the maintenance planning.
